Width of Ion and Monopole Tracks in Emulsion

Robert Katz and J. J. Butts

Kansas State University, Manhattan, Kansas

Submitted 13 July 1964; revised 14 September 1964

The width of the tracks of ions in emulsion has been calculated from the assumption that a developable image is formed when the energy dosage deposited by delta rays exceeds a threshold value, here found to be 6000 ergs/cm$^3$ in G-5 emulsion. The theory agrees with measurements of track width obtained by projecting track images to a magnification of 3000× and tracing around their outline, while truncating isolated delta rays at their bases. Agreement is to within a grain diameter to a range of about 4 cm. From the theory we infer that there is no $Z$ intelligence contained in the last 10 μ of track length, and that very poor resolution in $Z$ (above 15) is obtained in thin-down region (last 150 μ). The calculation has been extended to infer the width of the track of a Dirac monopole as a function of its range. The length of track required for discrimination between ions and monopoles depends on the monopole mass. Thus monopoles of mass 5 amu, unit pole strength ($137e / 2$), and energy 1500 MeV will have a range of 1000 μ and can be confused in width with ions of charge 20. On the other hand 3-amu unit-strength monopoles of 100-MeV energy will have a range of 100 μ and can be clearly distinguished from any ion. If 1 cm of track is available, any monopole (to mass 50 amu) can be clearly distinguished from all ions by the fact that its track width does not diminish with increasing range, and achieves a value of about 4 μ, in G-5 emulsion.

Width of Ion and Monopole Tracks in Emulsion

ROBERT KATZ AND J. J. BUTTS
Kansas State University, Manhattan, Kansas

(Received 13 July 1964; revised manuscript received 14 September 1964)

The width of the tracks of ions in emulsion has been calculated from the assumption that a developable image is formed when the energy dosage deposited by delta rays exceeds a threshold value, here found to be 6000 ergs/cm² in G-5 emulsion. The theory agrees with measurements of track width obtained by projecting track images to a magnification of 3000× and tracing around their outline, while truncating isolated delta rays at their lases. Agreement is to within a grain diameter to a range of about 4 cm. From the theory we infer that there is no Z intelligence contained in the last 10 μ of track length, and that very poor resolution in Z (above 15) is obtained in the thin-down region (fast 150 μ). The calculation has been extended to infer the width of the track of a Dirac monopole as a function of its range. The length of track required for discrimination between ions and monopoles depends on the monopole mass. Thus monopoles of mass 5 amu, unit pole strength (137ε/2), and energy 1500 MeV will have a range of 1000 μ, and can be confused in width with ions of charge 20. On the other hand 3-amu unit-strength monopoles of 100-MeV energy will have a range of 100 μ and can be clearly distinguished from any ion. If 1 cm of track is available, any monopole (to mass 50 amu) can be clearly distinguished from all ions by the fact that its track width does not diminish with increasing range, and achieves a value of about 4 μ, in G-5 emulsion.

I. INTRODUCTION

When the tracks of heavy ions were first detected in emulsion exposed to cosmic rays, in 1948, their width was thought to be proportional to ionization, and the wedge-shaped appearance of the tracks near the end of the range was attributed to electron pickup.

In 1953 Lonchamp¹ projected machine-accelerated ions into emulsion and found that it was necessary to clarify the distinction between ionization and width, for the width was decreasing at ranges where the ionization was increasing. Electron pickup occurred much too near the end of the range to be responsible for the wedge-shaped appearance of the tracks. He proposed a simple theory in which width was calculated as the diameter of a cylinder, centered on the ion's path, through whose surface 400 delta rays passed in each 100 μ of track length. By use of the delta-ray distribution formula, a range-energy relation for slow electrons, and an assumption of normal ejection of delta rays, a numerical value of track width could be computed. Though Lonchamp identified the mechanism of width formation, his formulation was not quantitative.

A substantial improvement in Lonchamp's theory was made by Bizzeti and Della Corte,² in 1959, by altering the track formation criterion from one of delta-ray flux to one of energy flux. At low ion energies, in the thin-down region, where delta rays emerging from the critical cylinder had a residual range less than a grain diameter, this theory was in reasonable agreement with experiment, but our extrapolation of the theory to higher ion energies yielded theoretical values for the track width which did not fit experimental data.

The present theory of track formation is built on the foundation of the work of Bizzeti and Della Corte. It assumes that charged particles transfer energy to a medium through the formation of delta rays, and that the detector is sensitized when these delta rays deposit energy in the medium at a rate exceeding a threshold dosage. In the case of emulsion, all photographic grains touching the cylinder of critical diameter are assumed to be sensitized. The track width is then the sum of the diameter of the critical cylinder, the diameter of a developed grain, and the diameter of an undeveloped grain (see Fig. 1). Processing is assumed to affect the width through the diameter of the developed grain, and possibly through the value of the threshold dosage.

Most detectors lack both the spatial resolution and the sensitivity for these detailed considerations of the mechanism of track formation to be significant. But, since electron-sensitive emulsion has both sensitivity and spatial resolution, the secondary ionization from delta rays in the tracks of heavy ions dominates the appearance of these tracks.

In the present calculation delta rays are assumed to be ejected with effective spherical symmetry, to obey a power-law 'diffusion-length' energy relation, and to have an energy spectrum in accordance with the usual delta-ray distribution formula. We are forced to treat the coefficient of the power law as an adjustable parameter, for want of complete data. Similarly, the threshold dosage for emulsion sensitization is treated as an

Width of Ion and Monopole Tracks in Emulsion

B 199

The track width may be calculated by postulating that an undeveloped grain will be sensitized if any part of its volume is sufficiently close to the path of the primary particle to receive the threshold dosage for latent image formation $E^*$. From symmetry, all grains included in and tangent to a cylinder of radius $x$ will be sensitized. On processing, the outermost grains will grow from diameter $D$ to a new diameter $GD$, so that the result of the range of delta rays is significantly less than a grain diameter, the minimum width achieved is $\lambda_0$, the sum of the diameters of a developed grain and an undeveloped grain. The formulation here is consistent with our observation that the track width in the first 10 $\mu$ is constant and is the same for all $Z$. We have observed that there are differences in $\lambda_0$ for tracks terminating at different depths in the emulsion, apparently due to processing.

At low ion energies where the range of delta rays is significantly less than a grain diameter, the minimum width achieved is $\lambda_0$, the sum of the diameters of a developed grain and an undeveloped grain. The formulation here is consistent with our observation that the track width in the first 10 $\mu$ is constant and is the same for all $Z$. We have observed that there are differences in $\lambda_0$ for tracks terminating at different depths in the emulsion, apparently due to processing.

If $E(x, \beta, Z)$ is the energy flux through a cylinder of radius $x$ carried by delta rays made by an ion charge $Ze$ and speed $\beta_c$, then the energy density deposited in a shell of thickness $\Delta x$ is $(E(x, \beta, Z) - E(x + \Delta x, \beta, Z))/(2\pi x \Delta x)$. In the limit of small $\Delta x$ we require that this expression approach a limit $E^*$, an adjustable parameter, so that

$$E^* = \frac{1}{2\pi x} \frac{\partial E(x, \beta, Z)}{\partial x},$$

and we must turn to the task of calculating $E(x, \beta, Z)$.

Let $\bar{W}(x, w)$ represent the average energy carried through a cylinder of radius $x$ by an electron of energy $w$, the average being with respect to the direction of emission. The total energy flux through the cylinder of unit length is obtained by integrating $\bar{W}dn$, where $dn$ is the number of delta rays per unit path length having energies between $w$ and $w + dw$, produced by an ion of effective charge $Ze$ moving with speed $\beta_c$. We have

$$dn = \frac{2\pi Ne^2 Z/dw}{m_e^2 \beta w^2} = C \frac{Z^2 dw}{\beta^2 w^2},$$

where the mass of an electron and its charge are $m$ and $e$, and $N$ is the number density of electrons in the medium (emulsion) through which the ion passes. The constant $C$ is implicitly defined in Eq. (4) as $C = 2\pi N e^2/(m_e c^2)$. We use observed trackwidths (corresponding to electrons of energy $w \approx 40$ keV) to simplify the rigorous delta-ray distribution formula which contains an additional factor of $(1 - \beta^2 w/w_{max})$. This factor is essentially $(1 - w/2m_e c^2)$, or nearly 1, for this calculation. This equation must be supplemented by an expression for the effective charge $Ze$ of an ion of atomic number $Z'$ at speed $\beta_c$ in emulsion; according to Barkas $^6$ $Ze$ may be expressed as

$$Ze = Z'e[1 - \exp(-125\beta/Z'^{2/3})].$$

Using Eq. (4) we obtain

$$E(x, \beta, Z) = \int_{u(x)}^{w_{max}} \bar{W}(x, w)dn = \frac{Z^2}{\beta^2} \int_{u(x)}^{w_{max}} \bar{W}(x, w) dw.$$ 

---

where the lower limit \( w(n) \), is the energy of a delta ray whose diffusion length is just sufficient to penetrate the cylinder if it is ejected normally, and the upper energy limit \( w_{\text{max}} = 2mc^2\beta^2\gamma^2 \), is the maximum delta-ray energy as determined by kinematics.

To complete the calculation we need a diffusion relation for low-energy electrons. Range-energy relations for electrons customarily give the maximum range or the extrapolated range expected from a population of monoenergetic electrons. The present calculation requires an average range. Since no data are available for the diffusion length at these low energies, we have altered an experimental power-law range-energy relation by treating its coefficient \( k \) as an adjustable parameter. We have

\[ r = Kw^a, \]

where \( r \) is the diffusion length in microns, \( w \) is the electron energy in keV. The exponent is taken to be 1.72, a value suggested by Glocker\(^7\) for energies between 1 and 100 keV.

For simplicity, delta rays are assumed to follow straight-line paths and their angular distribution is taken as effectively spherically symmetric. In the calculation a more relaxed angular distribution is actually used; that is,

\[ f(\theta) + f(\pi - \theta) = 1/2\pi. \]

The sum of the fore and aft electron-ejection probabilities is constant.

Reexpressing Eq. (7) as \( w = (r/k)^{1/a} \), and changing the variable in Eq. (6), we obtain

\[ E(x, \beta, Z) = \frac{CZ^a}{\alpha \beta^2} \int_x^{\infty} \frac{w(r) dr}{r}, \]

where the energy \( w \) of the delta ray has been written as \( w(r) \) for emphasis and where \( R = k(2mc^2\beta^2\gamma^2)^{1/a} \) is the maximum diffusion length of an electron. Bizzeti and Della Corte\(^3\) have shown that the integral in Eq. (9) is a function of the ratio \( x/R \) only. Thus we have

\[ E(x, \beta, Z) = \frac{CZ^a}{\alpha \beta^2} \left( \frac{x}{R} \right). \]

The track width may now be determined by applying the condition of constant dosage from Eq. (3). On writing

\[ I'(x/R) = \frac{\partial}{\partial x} \frac{x}{R}, \]

replacing \( C \) by its value and rearranging, we find

\[ \frac{Z}{\beta R \sqrt{E}} \left( \frac{N}{\sqrt{E}} \right)^{1/2} = \left[ -\frac{amc^2}{e^2} \frac{x}{R} \frac{1}{R} I'(x/R) \right]^{1/2}. \]

We have used this equation to plot a universal curve for the calculation of track width in emulsion, or in any detector (see Fig. 1). For G-5 emulsion, \( N = 1.045 \times 10^{24} \) electrons/cm\(^2\). For best fit with our track width data we have taken the threshold sensitivity of G-5 emulsion to electrons be 6000 ergs/cm\(^2\). Since the maximum diffusion length \( R \) is a function of \( \beta \), as previously given, we may find \( x \) from the curve for given values of \( \beta \) and \( Z \). To fit our data, \( k \) [Eq. (7)] was adjusted to 0.006.

Finally, accepted values of proton range\(^8\) are used in conjunction with Heckman’s formula\(^9\) to convert \( \beta \) to range for heavy ions, taking electron pickup into account. The results are plotted in Fig. 3.

III. EXPERIMENT, AND ITS CONNECTION WITH THEORY

The track width is subject to statistical fluctuations. To find an average width comparable to the computed width, we measure the area per unit length of a segment

---

of track which is long enough to smooth out the irregularities, but not so long that the average width changes appreciably in the segment. Ten-micron segments were used in the first 150 μ, and 50-μ segments were used at greater ranges.

Measurements were made by tracing around a projected image of the track, magnified 3000X by a Leitz nuclear-emulsion microscope provided with a xenon lamp. Disconnected clumps of silver were ignored and isolated delta rays were cut off at their base. The areas of the profiles traced in this manner were measured with a planimeter.

To normalize the data for variation in processing (grain size) with depth, the width of a track of 3-cr range was measured at different depths. Over small intervals at this large range, any width variation is due to variation of λ0 with depth in the emulsion. Through use of these measurements, all data were normalized to a depth of 150 μ by an additive correction.

The theoretical results indicate that the tracks of all ions have the same width λ0 in the last 10 μ of their range. This result is supported by our normalized data, and may be noted in published photographs. We have found that λ0 = 0.75 μ, in our emulsions, a value consistent with average data for G-5 emulsion given by Barkas, who gives the diameter of a developed grain as 0.5 μ and the diameter of an undeveloped grain as 0.27 μ.

The combination of parameters yielding the best fit to our data are $E^* = 6000 \text{ ergs/cm}^3$, and $k = 0.006$ [see Eq. (7)]. Our determination of $k$ gives a diffusion length which is about one-third the maximum range of 10-keV electrons, as given by Feldman.

Width measurements were made on eight tracks found in emulsion exposed to cosmic rays at an altitude of 100000 ft. The results are shown in Figs. 4 and 5, plotted together with the theoretical curves for the best estimate of $Z$, and for $Z \pm Z^{1/2}$ to show discrimination. Most of the measured tracks agree with the theory to within a grain diameter (0.5 μ) at all ranges to 4 cm.

In all calculations the ion mass was taken as that of the most abundant isotope. Comparison of the theory with published data for the width of machine accelerated ions is shown in Figs. 6 and 7, where the published data of Bizzeti and Della Corte and of Skjeggestad are plotted over our theoretical curves.

Data and theory show that the range at which the width of an ion track is a maximum is substantially independent of $Z$. It appears that the best $Z$ discrimination should be obtained when measurements are made near the maximum width. The roughness of the track outline in this region is offset by the slower variation of width with range (as compared to the thin-down region of the track), allowing measurement of longer segments.

The theory predicts that the width-range curves of ions of different $Z$ cross in the thin-down region. For ranges less than 150 μ, a plot of reduced width $(λ - \lambda_0)$ versus $Z$ shows a maximum (see Fig. 8). This effect is easily understood in terms of the width limitation imposed by the maximum diffusion length of delta rays. In the thin-down region the very large number of delta rays per unit track length causes the theoretical

---

width to be approximately equal to the diffusion length of the electrons of maximum energy. Thus, in the thin-down region the width is almost proportional to $\beta^2$. At a range of, say, 50 $\mu$, the speed of an ion of $Z=50$ is less than that of a $Z=20$ ion. This is due to electron pickup: a $^{60}$Co ion has an extra range of 120 $\mu$ and a $^{60}$Sn ion has an extra range of 360 $\mu$ over the range otherwise predicted from proton ranges. The track of the lighter ion is therefore wider than the track of the heavier ion. These considerations imply that $Z$ assignments based on width, or on the area of the thin-down wedge, are insensitive to $Z$ and are ambiguous above $Z=15$. The situation is vastly improved at a range of 150 $\mu$.

### IV. WIDTH OF MONOPOLE TRACKS

A slowly moving monopole of pole strength $g$ generates an electric field normal to the trajectory of magnitude $g\beta/e^2$, where $r$ is the distance to the field point, and $\beta$ is the impact parameter. We expect a monopole to interact with matter through this field. A slowly moving charge carries with it an electric field whose component normal to the trajectory is $Ze\beta/e^2$. A comparison of these fields suggests that formulas for ionization and delta-ray distribution for moving ions can be converted to formulas appropriate to monopoles by replacing $Ze$ by $g\beta$. This recipe was derived rigorously by Bauer\textsuperscript{13} and by Cole\textsuperscript{14} in 1951.

We may find an expression for the delta ray distribution for monopoles by making the substitution $g\beta$ for $Ze$ in Eq. (4) to obtain

$$dn=C(\varepsilon/\varepsilon')(dw/w^2).$$  \hspace{1cm} (12)

The delta-ray distributions for charges and poles are plotted in Fig. 9. Note that the delta-ray distribution formula remains valid at high energies, because of compensating factors of $\gamma$ which appear at high speeds from the Lorentz contraction and time dilation.\textsuperscript{14} In Fig. 9, curve $A$ is the delta-ray distribution for a Dirac monopole (the kinematic cutoff depends on $\beta$ and is shown as a dashed line for $\beta=0.25$ at $W=68$ keV). The other two curves show the variation in the delta-ray distribution with $\beta$ for ions of $Z=16$. It is significant that the delta-ray distribution for poles depends on $\beta$ only through the changing value of the kinematic cutoff.

An increase in $\beta$ adds more delta rays of higher energy leaving the rest of the distribution unchanged. Thus, an increase in $\beta$ cannot produce a decrease in track width. The width of a monopole track must increase monotonically with $\beta$, independent of the detailed mechanism by which a track-width theory converts the delta-ray distribution to track width.

A universal curve for determining monopole track width as a function of $\beta$ may be obtained by making the substitution $g\beta=Ze$ in the abscissa label of Fig. 2. A universal curve for determining monopole track width as a function of $\beta$ may be obtained by making the substitution $g\beta=Ze$ in the abscissa label of Fig. 2.

To establish a range-$\beta$ relation for monopoles, the ionization formula of Bethe\textsuperscript{18} was integrated, making shell corrections according to the procedure of Vigneron.\textsuperscript{17} The resulting range values were found to be

\textsuperscript{16} M. S. Livingston and H. A. Bethe, Rev. Mod. Phys. 9, 245 (1937).
\textsuperscript{17} P. L. Vigneron, J. Phys. Radium 14, 145 (1953).
in agreement with experimental data for protons of $\beta < 0.9$ to within 5%. The ionization formula was then converted by the usual recipe ($Ze \rightarrow g\beta$) and integrated to give range-$\beta$ values for monopoles. Our calculations of monopole range were in agreement with a curve of Amaldi et al. There is some question about the interaction of poles with the medium in the limit of low velocity, when the electric field of the moving pole drops to zero. We infer from arguments by Malkus and others that a pole will interact strongly with matter when its energy is of the order of tens of electron volts, and that the range we have calculated here is within a few microns or within 5% of the true range, whichever is greater.

The results of these calculations are plotted in Fig. 10, where the reduced width $(\lambda - \lambda_0)$ of the tracks of Dirac monopoles of unit strength $(137e/2)$ and of twice unit strength $(137e)$ is plotted against a background of track-width-range curves for ions.

The most obvious feature of the monopole track is the absence of a maximum width, a feature which is required by the delta-ray distribution relation for poles, Eq. (12), independent of other aspects of the track-width theory. The track of a monopole is strongly dependent on its mass and its magnetic charge, as shown in Fig. 10. The range at which the track reaches saturation width is determined by the mass of the monopole, while the magnitude of the saturation width is determined by the pole strength.

Fig. 9. The spectrum of delta rays in G-5 emulsion for unit Dirac monopoles (curve A) and for $Z = 16$ ions at $\beta = 0.2$ and 0.3. The delta-ray spectrum for poles is the same for all $\beta$, except for the position of the kinematic cutoff, shown as a dashed line at $\omega = 68$ keV for $\beta = 0.25$.

Fig. 10. Comparison of the width of tracks of ions ($Z = 3, 10, 20, 50$) and monopoles of unit pole strength and twice unit pole strength in G-5 emulsion. The family of monopole curves (heavy lines) includes the anticipated track width for a monopole of strength $g = 137e$ and $m = 10$ amu (curve A), and of $g = 68.5e$ with $m = 3$ amu (curve B), $m = 5$ amu (curve C), and $m = 10$ amu (curve D).

The region of possible confusion with ions depends on the mass assumed for the monopole. For masses less than 3 amu, the largest possible mass obtainable in recent accelerator experiments, monopoles would be easily identified if only the last 50 $\mu$ of track were available. Monopoles with mass greater than 10 amu would be clearly distinguished from ions if 500 $\mu$ of track were available for measurement. For other masses, a pole might be confused with an ion on the basis of track-width measurements to ranges of 1000 $\mu$. For example, a 5-amu pole and a $Z = 20$ ion display nearly the same range-width relation to 1000 $\mu$.

In a recent paper Goto has predicted that monopoles from cosmic space would be accelerated to energies of $10^{20}$ eV. Monopoles of these energies may be expected to display a constant track width of approximately 4 $\mu$ in G-5 emulsion, according to these calculations, and should be readily identifiable.

ACKNOWLEDGMENTS

We are grateful to D. E. Guss for the emulsion used in these measurements. We are also indebted to E. W. Hoffman and M. R. Querry for their help in the calculations, and especially to E. J. Kobetich for his help in measurement and machine computation.
